Abstract

Background

RNA-Seq is revolutionizing the way transcript abundances are measured. A key challenge in transcript quantification from RNA-Seq data is the handling of reads that map to multiple genes or isoforms. This issue is particularly important for quantification with de novo transcriptome assemblies in the absence of sequenced genomes, as it is difficult to determine which transcripts are isoforms of the same gene. A second significant issue is the design of RNA-Seq experiments, in terms of the number of reads, read length, and whether reads come from one or both ends of cDNA fragments.

PROCEDURE

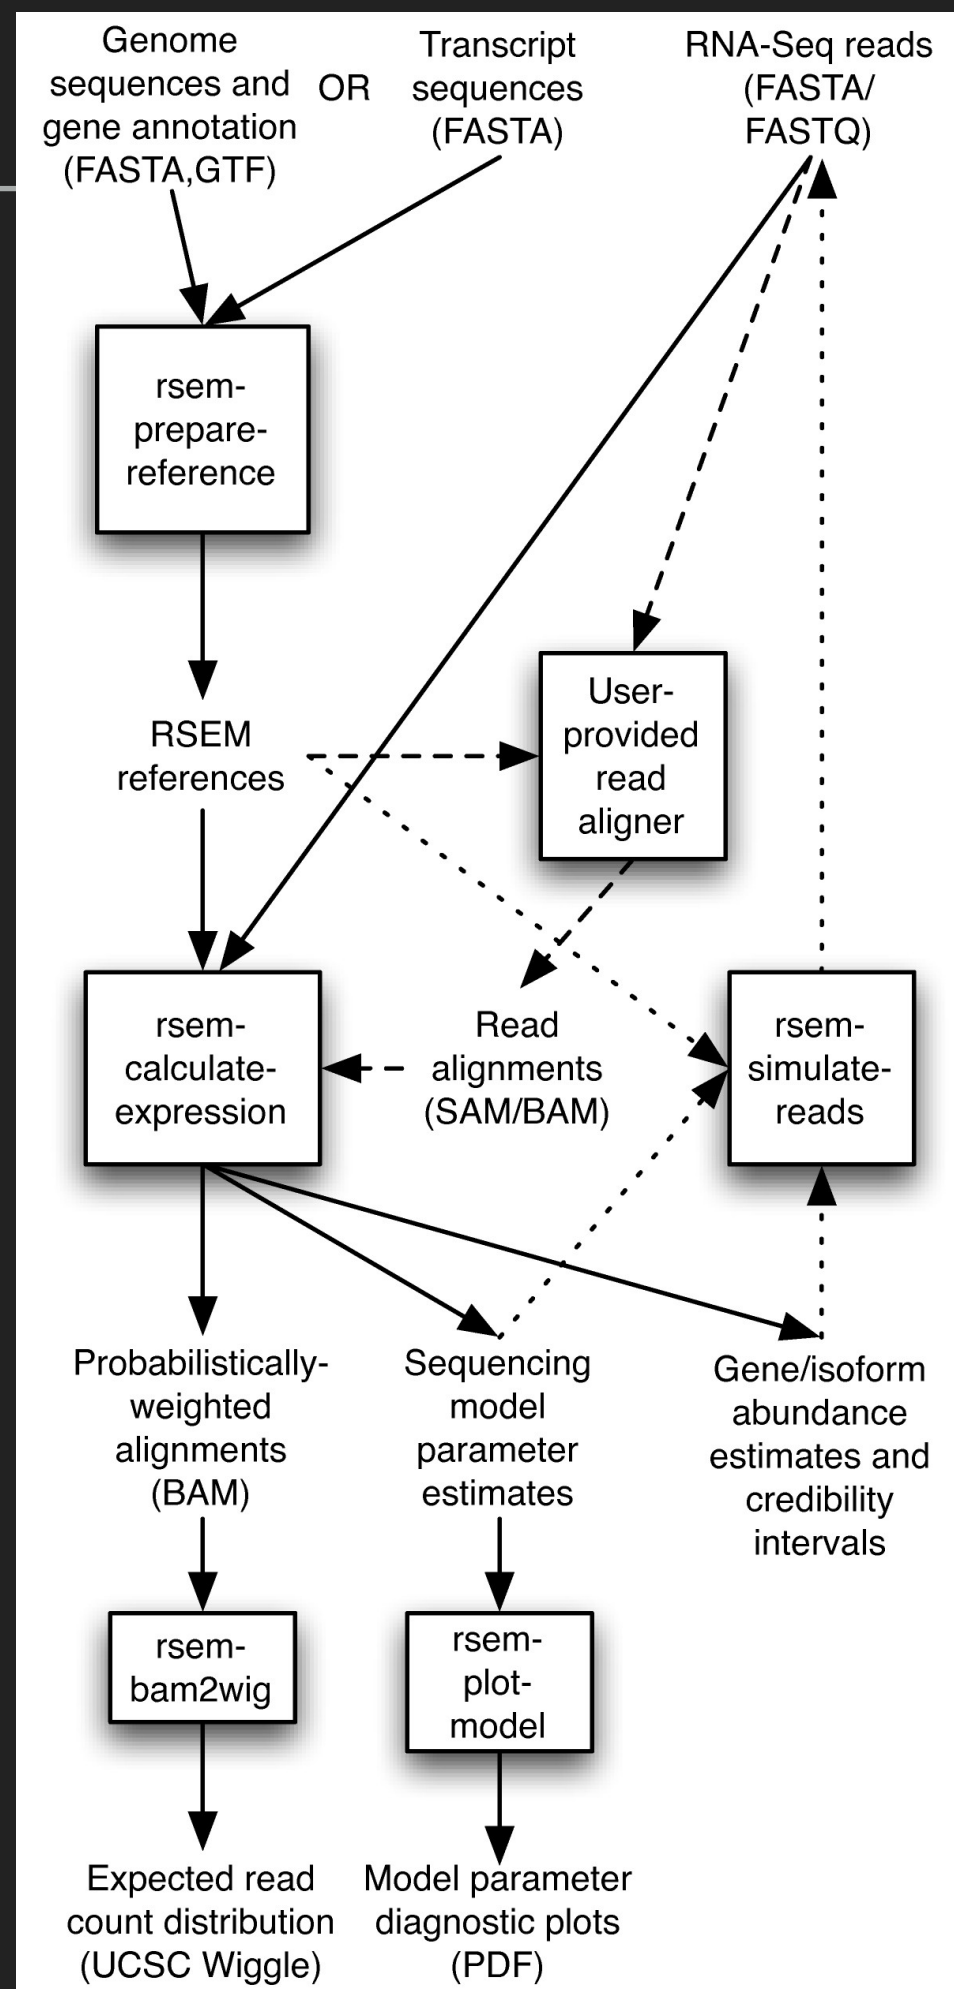

- ▶ First, align a set of RNAseq reads to the reference transcripts (using Bowtie).
- ▶ The resulting alignments are used to estimate abundances and their credibility intervals.
- ▶ Done with a Trinity wrapper script:
 - ▶ `align_and_estimate_abundance.pl`
 - ▶ must be done separately for each replicate/treatment!

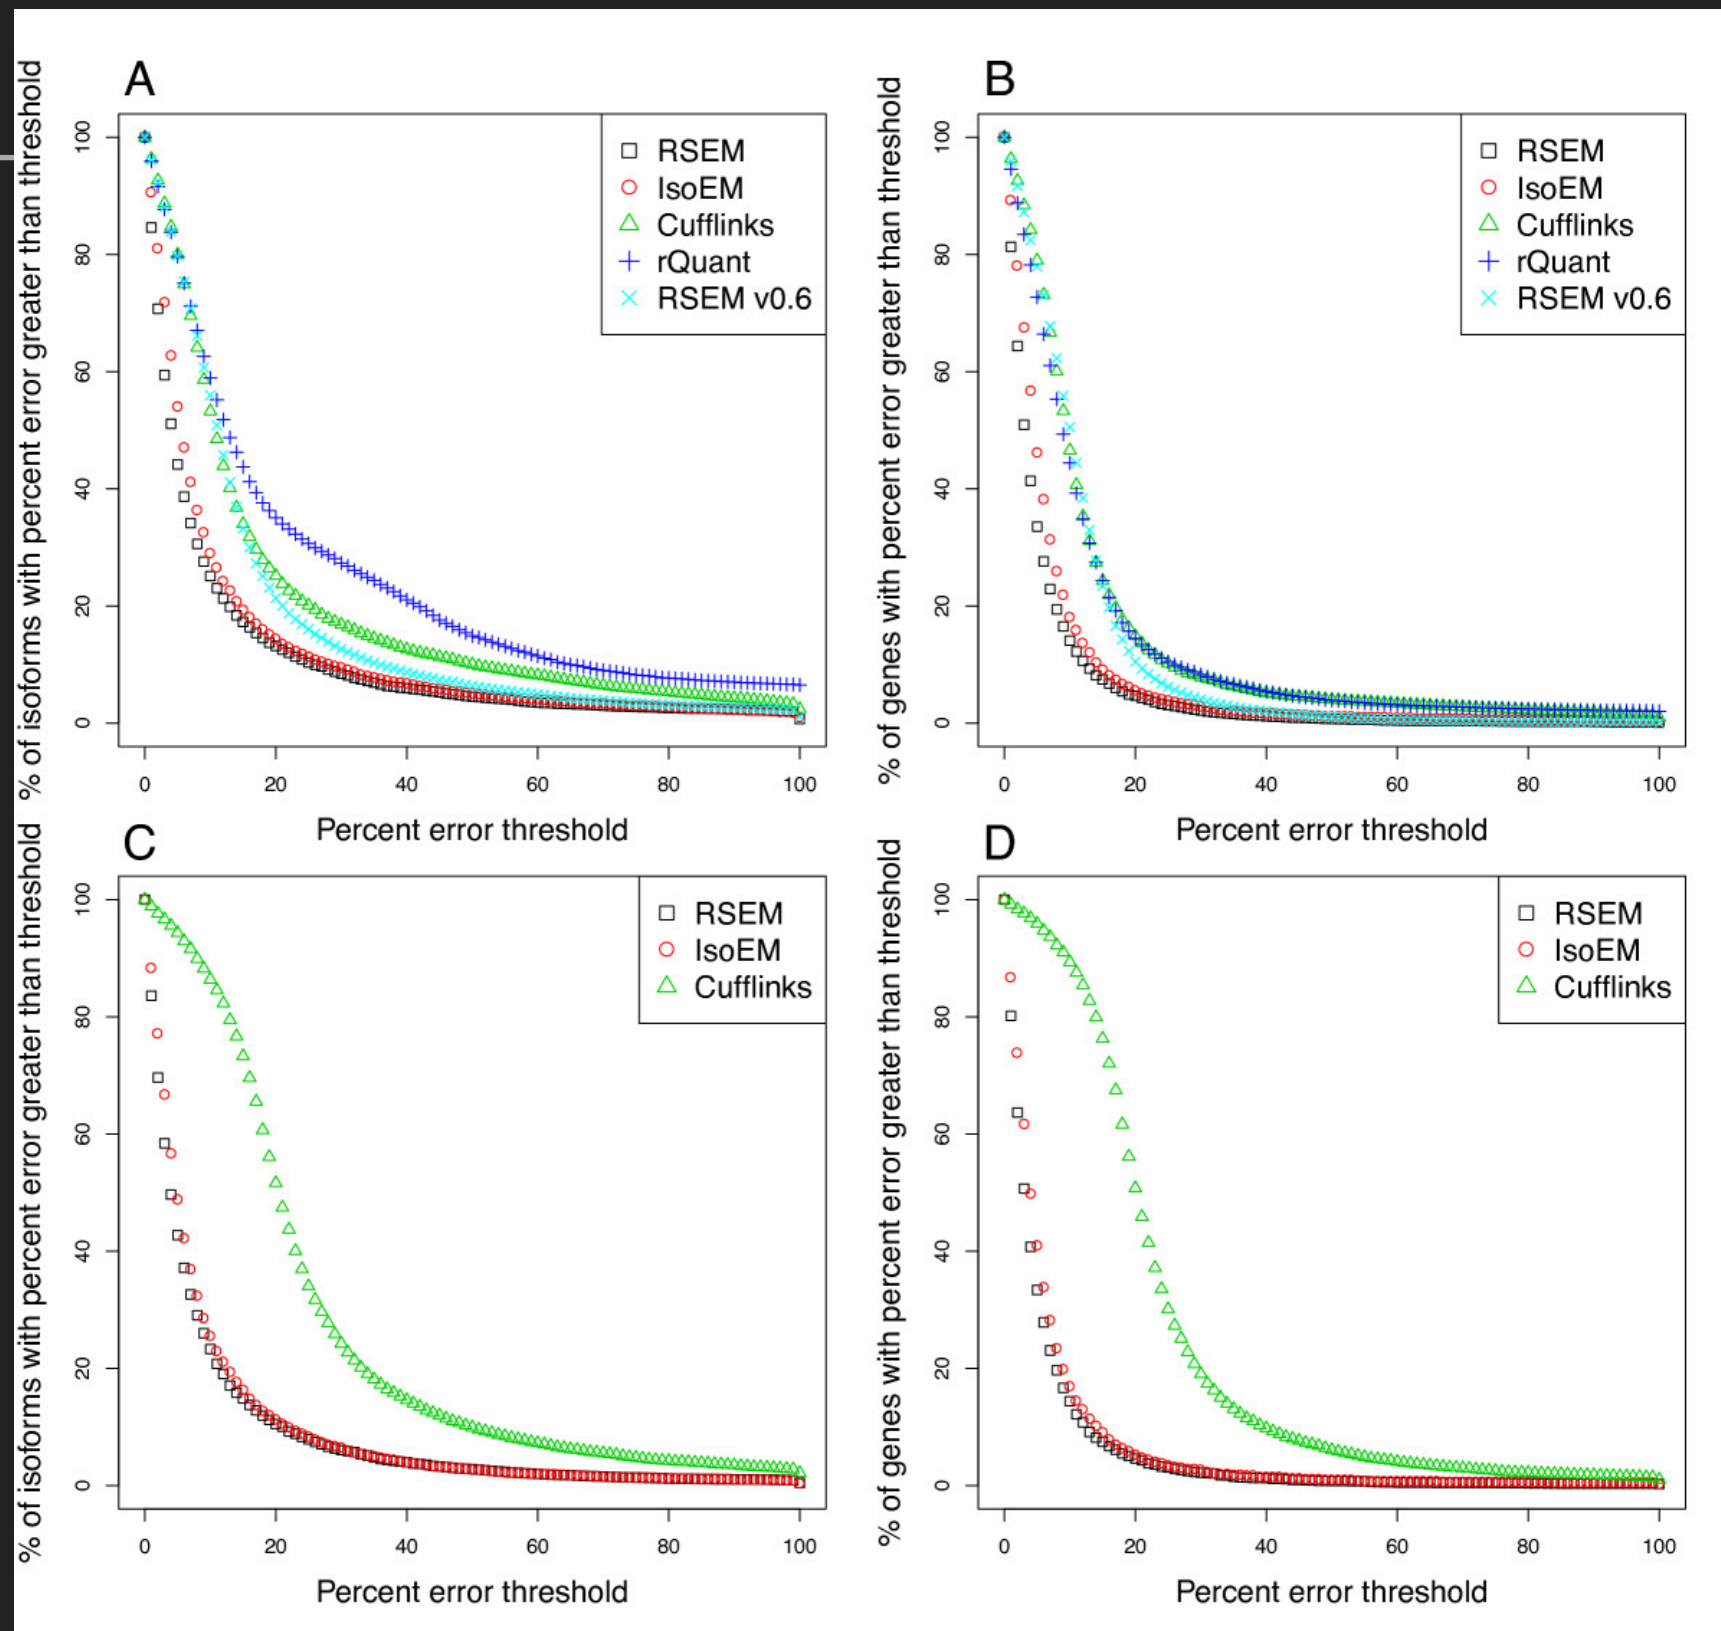

Nature Protocols **8**, 1494–1512 (2013) | doi:10.1038/nprot.2013.084

Published online 11 July 2013

An illustrative example of abundance estimation for two transcripts with shared (blue) and unique (red, yellow) sequences. To estimate transcript abundances, RNA-seq reads (short bars) are first aligned to the transcript sequences (long bars, bottom). Unique regions of isoforms will capture uniquely mapping RNA-seq reads (red and yellow short bars), and shared sequences between isoforms will capture multiply-mapping reads (blue short bars). An expectation maximization algorithm, implemented in the RSEM software, estimates the most likely relative abundances of the transcripts and then fractionally assigns reads to the isoforms based on these abundances. The assignments of reads to isoforms resulting from iterations of expectation maximization are illustrated as filled short bars (right), and eliminated assignments are shown as hollow bars. Note that assignments of multiply-mapped reads are in fact performed fractionally according to a maximum likelihood estimate. Thus, in this example, a higher fraction of each read is assigned to the more highly expressed top isoform than to the bottom isoform.

- Accuracy of four RNA-Seq quantification methods. The percent error distributions of estimates from RSEM, IsoEM, Cufflinks, and rQuant on simulated RNA-Seq data. The error distributions of global isoform and gene estimates from PE data are shown in (A) and (B), respectively. Global isoform and gene estimate error distributions for SE data are shown in (C) and (D), respectively.

OUTPUT

- ▶ The primary output generated by RSEM is the file containing the expression values for each of the transcripts.

TRINITY_DN108_c1_g1	TRINITY_DN108_c1_g1_i1	195.00	180.98	0.00	0.00	0.00

OUTPUT

transcript_id	gene_id	length	effective_length	expected_count	TPM	FPKM	IsoPct
TRINITY_DN0_c0_g1_i1	TRINITY_DN0_c0_g1	328	198.75	29.00	9093.16	43883.19	100.00
TRINITY_DN0_c0_g2_i1	TRINITY_DN0_c0_g2	329	199.75	0.00	0.10	0.48	100.00

- ▶ **expected_count**: number of RNA-Seq fragments predicted to be derived from that transcript
- ▶ **FPKM**: fragments per kilobase of cDNA per million fragments mapped
- ▶ **TPM**: transcripts per million

- ▶ The next step is to take expression estimates and normalize across samples.

METHOD

OPEN ACCESS

A scaling normalization method for differential expression analysis of RNA-seq data

Abstract

The fine detail provided by sequencing-based transcriptome surveys suggests that RNA-seq is likely to become the platform of choice for interrogating steady state RNA. In order to discover biologically important changes in expression, we show that normalization continues to be an essential step in the analysis. We outline a simple and effective method for performing normalization and show dramatically improved results for inferring differential expression in simulated and publicly available data sets.

TMM

- ▶ The trimmed mean of M-values normalization method: The total RNA production, S_k , cannot be estimated directly, since we do not know the expression levels and true lengths of every gene. However, the relative RNA production of two samples, $f_k = S_k / S_{k'}$, essentially a global fold change, can more easily be determined. We propose an empirical strategy that equates the overall expression levels of genes between samples under the assumption that the majority of them are not DE. One simple yet robust way to estimate the ratio of RNA production uses a weighted trimmed mean of the log expression ratios (trimmed mean of M values (TMM)).

- Normalization is required for RNA-seq data. Data from [6] comparing log ratios of (a) technical replicates and (b) liver versus kidney expression levels, after adjusting for the total number of reads in each sample. The green line shows the smoothed distribution of log-fold-changes of the housekeeping genes. (c) An M versus A plot comparing liver and kidney shows a clear offset from zero. Green points indicate 545 housekeeping genes, while the green line signifies the median log-ratio of the housekeeping genes. The red line shows the estimated TMM normalization factor. The smear of orange points highlights the genes that were observed in only one of the liver or kidney tissues. The black arrow highlights the set of prominent genes that are largely attributable for the overall bias in log-fold-changes.
